Abstract

We develop a simple theoretical model showing that, by adding to the adjustment costs associated with permanent contracts, local social pressure against dismissals creates an incentive for CEOs to rely on fixed-term contracts, in an attempt to escape social pressure. Using linked employer-employee data, we show that establishments located closer to headquarters have higher shares of fixed-term contracts in hiring than those located further away whenever firms' headquarters are located in self-centered communities and the CEO not only works but also lives there. We show that these findings can only be explained by local social pressure.

Keywords: social pressure, employment contracts, adjustment costs, CEO reputation

Introduction

Fixed-term contracts account for a very large share of new hires in many OECD countries. The literature suggests that whether firms choose to hire workers on temporary rather than permanent contracts depends on the adjustment costs associated with either type of contract. The determinant of the difference in adjustment costs across contracts mostly emphasized in the literature is the gap in legal constraints on terminations: the higher the legal cost of firing workers on permanent contracts as compared to terminating a fixed-term contract, the stronger the incentive for firms to hire temporary workers as a way to reduce adjustment costs (e.g. Boeri and Van Ours, 2013).

However, the share of fixed-term contracts in hiring is large even in countries where legal firing costs are low. For example, in the United Kingdom the share of fixed-term contracts in new hires is as large as 25% (OECD, 2016), while the legal cost of firing workers on open-ended contracts is the third lowest among all OECD countries, after the United States and New Zealand. This suggests that relative adjustment costs on permanent vs fixed-term contracts are not solely determined by legal constraints.

In this paper, we consider another potential determinant of relative adjustment costs, namely social pressure. There is evidence in the literature that social pressure against dismissals creates an incentive for firms to avoid firing workers employed on permanent contracts (Landier, Nair and Wulf, 2009; Bassanini, Brunello and Caroli, 2017). If social pressure increases the relative adjustment costs associated with permanent contract terminations, firms should have a stronger incentive to hire workers on fixed-term contracts. Termination of these contracts is indeed less subject to social pressure because they involve no implicit commitment to long-term employment (Rousseau and Anton, 1988; Charness and Levine, 2000). Moreover, hiring being hardly visible to observers,¹ employers are unlikely to feel pressure for hiring on permanent rather than fixed-term contracts.

In this paper, we consider the social pressure that local communities put on Chief Executive Officers (CEOs) to avoid dismissals in their immediate surroundings. Social pressure refers here to the threat of social sanctions exerted by the local community of the CEO, which may take the form e.g. of a loss of reputation within the community. It has been shown in the literature that individuals want to be liked and respected by others (see e.g.

¹ While news about dismissals looms large in the media (e.g. Friebel and Heinz, 2014), news about hiring usually does not appear on the press. Evidence of this is provided by Heinz and Swinnen (2015) who review articles reporting on downsizing and upsizing in a leading German newspaper over 8 years. On a per-job basis, they find 20 times as many articles reporting on job destruction as articles reporting on job creation.

Benabou and Tirole, 2006). Moreover, direct interactions with others have been shown to generate social pressure, thereby affecting individuals' behavior (Della Vigna, List and Malmendier, 2012). This is likely to be the case for CEOs when making human resource management choices, and, in particular, firing decisions. Bandiera et al. (2015) suggest that, beyond profits, CEOs indeed draw utility from non-monetary rewards, including reputation within and respect from the community.² In this paper, we build on previous evidence showing that CEOs avoid harming their own community by making workers redundant locally, by fear of the social sanction that this could entail, for example through a lack of respect.³ We model and test the idea that, in an attempt to escape the social sanction associated with dismissals, firms hire workers on fixed-term rather than permanent contracts.

We first present a simple theoretical model in which employment decisions are taken by the CEO at the firm's headquarters. This assumption is justified by the fact that, in most OECD countries (see OECD, 2013), firing decisions in different plants must be coordinated at the firm level since the threshold that triggers (more expensive) collective redundancy procedures is defined on the basis of the total number of dismissals undertaken in all establishments of the firm.⁴ In our model, whether the CEO decides to hire workers on permanent or fixed-term contracts depends on the probability that the job becomes unproductive and on the relative adjustment costs associated with each type of contract. We allow the difference in adjustment costs across contracts to be affected by the social pressure exerted on the CEO by the local community at the firm's headquarters. The intensity of this pressure depends on the characteristics of the local community. When the community is self-centered, it cares about dismissals only if they affect the community itself or individuals with whom it is closely connected. To the extent that social interactions decrease with distance, this generates a negative relationship between distance to headquarters and social pressure, and hence a negative relationship between distance and the incentive for firms to hire workers on fixed-term contracts in an attempt to circumvent social pressure. In contrast, when the local community at headquarters is outward-looking, it cares about dismissals wherever they

² They report the following statement by a firm owner/manager: "I'd rather be worth 100 million euros (...) and enjoy people's respect when I am the senile chairman of my firm than be worth a billion". The importance of being part of a community is also emphasized by Gianni Agnelli, the former CEO of Fiat: "[The] rooting in a community, in its culture, and in its values is an integral part of the identity of a company. And it leads to incorporating attention and sense of responsibility towards the community, including its problems and its development expectations, in the entrepreneur's behavior and choices" (Talk given at the Twelfth World Conference FBN in Rome in 2001. Our translation).

³ See references in the previous paragraph.

⁴ The United States and the United Kingdom, where this threshold is defined at the establishment rather than the firm level, are exceptions.

take place, which implies that the social pressure perceived by the CEO is the same no matter at which distance firings occur.

Our empirical analysis relies on French data. We match two large datasets. The *Déclarations Annuelles des Données Sociales* (DADS) contains social security records for all plants and firms in the non-agricultural business sector, including the geographical location of the plants and firms' headquarters. The *Déclarations des Mouvements de Main d'Oeuvre* (DMMO-EMMO) has quarterly hiring by type of employment contract for all plants with 50 workers or more and a 25% random sample of those between 10 and 50 workers. By matching these datasets, we obtain information on the geographical dispersion of employment contracts for almost 5,000 multi-establishment firms and over 23,000 plants for the period 1998-2009.

Our empirical analysis takes into account the potential endogeneity of distance to headquarters by instrumenting actual distance with potential distance. The latter is defined as the distance from the headquarters at which the establishment would have been located had its location been chosen only to maximise its contribution to the market potential of the firm (measuring the capacity of the firm to serve large local markets while minimising transport costs).

We provide evidence separately for firms with headquarters located in self-centered and outward-looking communities. Our main measure of self-centeredness is based on the difference in *département*-level turnout rates between local and national elections.⁵ We validate this measure by showing that it strongly correlates with a more standard measure of self-centeredness provided by the European Value Study (EVS, 2010), but available only at a coarser level of aggregation (i.e. administrative regions). We show that, for firms with headquarters located in self-centered communities, the impact of distance to headquarters on the share of fixed-term contracts in hiring is negative and statistically significant. We find no such evidence for firms with headquarters located in outward-looking communities. We then consider the impact of firm visibility at headquarters on the share of fixed-term contracts. The underlying assumption is that CEOs are subject to social pressure arising from their local community only if their firm is visible enough, i.e. represents a large-enough share of local employment in the area of the headquarters. We show that when firms' headquarters are located in self-centered communities, the negative impact of distance on the share of fixed-term contracts is concentrated on firms that are highly visible. We also investigate the role of

⁵ *Départements* are administrative subdivisions larger than municipalities but smaller than regions.

the CEO's place of living. We expect CEOs to be more sensitive to the social pressure arising from the community at headquarters when they also live (and not only work) in that community. We show that the negative impact of distance on the share of fixed-term contracts that we observe when firms' headquarters are located in self-centered communities is indeed driven by CEOs who live in that community.

In the light of our model, we can interpret these findings as indirect evidence indicating that when social pressure against dismissals is strong, firms tend to hire workers on fixed-term contracts to escape it. We discuss alternative explanations of a negative relationship between distance and the share of fixed-term contracts and we show that none of them can account for the whole set of results that we obtain. We also discuss the nature of the social pressure exerted on CEOs and show that the main mechanism consistent with our findings is the fear of reputational loss.

Our paper relates to several strands of literature. The first one is the literature on the choice of labor contracts at the time of hiring. The first generation of theoretical papers on this topic has much emphasized the role of hiring and firing regulations in determining differences in adjustment costs between permanent and temporary contracts. These papers show that employers prefer to hire on temporary contracts whenever legal firing costs are higher than the sum of legal hiring and termination costs for fixed-term contracts (e.g. Blanchard and Landier, 2002; Cahuc and Postel-Vinay, 2002). The most recent literature emphasizes the role of other factors – such as differences across jobs in the risk of being hit by a negative shock or in the attractiveness of each type of contract – but these factors would not induce hiring on fixed-term contracts if there were no difference in legal adjustment costs across contracts (e.g. Berton and Garibaldi, 2012; Faccini, 2014; Cahuc, Charlot and Malherbet, 2016). Empirical evidence provides ample confirmation of the role of firing legislation – as well as of effective restrictions on hiring on fixed-term contracts – in determining the distribution of the different types of contract (e.g. Autor, 2003; Kahn, 2010; Centeno and Novo, 2012; Bentolila et al., 2012).⁶ We contribute to this literature by showing that firms may resort to fixed-term contracts also in order to escape social pressure against dismissals, which represents an independent explanation from the existence of differences in legal adjustment costs.⁷

⁶ Recent empirical evidence has also shown that firms resort more to fixed-term contracts when they have a greater risk of job destruction (Dräger and Marx, 2017; Devicienti, Naticchioni and Ricci, 2018).

⁷ There is also evidence in the literature that hiring decisions may seem somewhat arbitrary. Hoffman, Kahn and Li (2018) show that managers may discard relevant information about applicants when hiring, which leads to

Our paper also speaks to the literature on social pressure and individual behavior, such as image-motivated altruism. Research in this field suggests that individuals want to be liked and respected and that they seek to gain social approval of their behavior (see Benabou and Tirole, 2006; Andreoni and Petrie, 2004; Ariely, Bracha and Meier, 2009). In fact, behaviors that may seem altruistic are often the result of attempts made by selfish individuals to escape the threat of social sanctions (Della Vigna et al., 2012). This suggests that apparent altruism is partly image-motivated and that individuals are sensitive to the social pressure arising from their immediate social environment. Beyond altruism, there is evidence that social pressure also affects other dimensions of individual behavior, such as civic attitude as regards voting (Gerber, Green and Larimer, 2008; Funk, 2010) or tax compliance (Battiston and Gamba, 2016). Social pressure has also been shown to influence firm behavior. This pressure may be exerted by consumers (e.g. Baron, 2011; Hendel, Lach and Spiegel, 2017). It may also arise from inside the firm. As shown in the literature on corporate governance – e.g. Bertrand and Mullainathan (2003), Giroud and Mueller (2010) and Cronqvist et al. (2009) – when managers are entrenched, they react to social pressure from employees by paying them higher wages than the profit-maximising level. A last strand of literature, to which this study belongs, shows that social pressure may also arise from the local community where the firm headquarters are located. As a reaction, firms tend to concentrate employment reductions, and in particular dismissals, in plants located further away from headquarters – see Landier et al. (2009), Abraham, Goesaert and Konings (2014) and Bassanini et al. (2017). In this paper, we show that firms not only put up with social pressure. They actually implement human resource management strategies to escape it, in particular by hiring employees on fixed-term rather than on permanent contracts.

The rest of the paper is structured as follows. Section I presents a simple model of social pressure and choice of employment contracts. Section II lays out our empirical strategy. Section III describes the data and presents summary statistics. Section IV presents the empirical results. Alternative explanations are discussed in Section V and Section VI concludes.

1. Social Pressure and Labor Contracts: a Simple Model

lower quality hires. They interpret this finding as the outcome of managerial biases or errors. Our results suggest that one possible explanation of these biases or apparent errors may be the sensitivity of CEOs (or top managers) to local social pressure.

We consider a multi-establishment company where employment decisions are taken at the headquarters. We focus on the choice of employment contracts as the distance to the headquarters increases. We assume, for the sake of simplicity, that in each secondary establishment j each new job i has the same productivity (normalised to 1) but a different level of risk⁸. Following Cahuc et al. (2016), job risk, denoted by $\gamma > 0$, is the probability that at each period the job becomes unproductive and is destroyed. It is drawn, upon recruitment, from a distribution with cumulative distribution function $F_j(\gamma)$. It is observed by the firm and is the basis of its contract decision. Finally, we assume that job risks are independent within a given establishment.

Management decisions, including hiring and termination of contracts, are taken by the CEO who works at the headquarters.⁹ We assume that establishments located further away from the headquarters are more difficult to monitor and that CEOs have imperfect information on their local conditions. This heightens the risk of negative productivity shocks leading to job destruction in distant establishments. There is indeed abundant evidence that monitoring problems and asymmetric information induce a positive relationship between the probability of downsizing and the distance to the headquarters (see e.g. Landier et al., 2009, Giroud, 2013, Kalnins and Lafontaine, 2013, and Charnoz, Lelarge and Trevien, 2018). As a consequence, we assume that job risk increases with the distance δ between the establishment and the firm's headquarters¹⁰ – i.e. the distribution of γ shifts upward:

$$\frac{\partial F_j(\gamma)}{\partial \delta_j} = \frac{\partial F(\gamma, \delta_j)}{\partial \delta_j} < 0 \quad [1.1]$$

When meeting with a worker, the CEO has to decide whether or not to hire his/her and the type of contract to be chosen between two alternatives: a permanent contract and a fixed-term contract of duration D .¹¹ Writing a contract induces a strictly positive cost, h^o or h^f , for permanent or fixed-term contracts, respectively. Employees on permanent contracts can be dismissed by paying a legal firing cost d^o . No legal cost is associated with termination of

⁸ Taking into account productive heterogeneity would not change our predictions.

⁹ Our assumption is that employment decisions are taken centrally at headquarters. For the sake of simplicity, we represent these decisions as taken by the CEO even if, in practice, they may also be taken by other top executives.

¹⁰ We do not model here why a firm has at least one plant beyond the headquarters, and why plants may be located at different distances from headquarters.

¹¹ We assume here that there is a unique possible duration D defined by the law. In many countries the maximum duration of fixed-term contracts, including possible renewals, is indeed fixed by the law (see e.g. OECD, 2014).

fixed-term contracts. By law, however, it is impossible to fire a worker before the end of a fixed-term contract.¹²

Near each establishment and the headquarters lives a community. Following Akerlof (1980), we assume that the CEO cares about profits and his/her reputation. A community can sanction the CEO when he or she is perceived as harming it. Sanctions take the form of a reduction in the CEO's reputation within the community. We also assume that CEOs are sensitive only to social sanctions taking place in their local environment, i.e. in the area of the headquarters.¹³

The CEO's intertemporal utility from a job i in establishment j is the sum of the expected instantaneous profits minus contracting and legal costs as well as social sanctions undergone in the case of dismissal. We assume that hiring on (or termination of) fixed-term contracts does not entail any social sanction. Social sanctions indeed result both from (i) the refusal of the CEO's behavior by the community and (ii) the visibility of this behavior since a behavior cannot be disapproved if it is unknown to the community. The choice to hire workers on fixed-term contracts is unlikely to be visible to the community since the literature provides evidence that job creations themselves are hardly visible. Heinz and Swinnen (2015) review articles reporting on downsizing and upsizing in a leading German newspaper over 8 years. On a per-job basis, they find 20 times as many articles reporting on job destruction as articles reporting on job creation. Similarly, Bassanini et al (2020) study the reactions on Twitter to large-scale job-destruction and job-creation events announced on the UK press. They find that negative reactions to job-destruction announcements are much more numerous and fiercer than the positive reactions to job-creation announcements. These findings suggest that job creations go largely unnoticed and, a fortiori, the type of employment contracts on which employees are hired. Therefore, local communities do not have the relevant information that would allow them exerting significant social pressure against hiring on fixed-term contracts. As regards the termination of fixed-term contracts, it is unlikely to trigger strong disapproval from the community even when noticed since, as argued in the literature (see Rousseau and Anton, 1988; Charness and Levine, 2000), terminations are considered unfair only in case of commitment to long-term employment, which does not hold for fixed-term contracts. In any case, what we make here is only a simplifying assumption and the main predictions of the model still hold if communities impose a social sanction on CEOs in the

¹² Cahuc et al. (2016) make the same assumption, which corresponds to the French legislation in which a fixed-term contract cannot be breached. However, lifting this assumption would not change the results provided that there are positive hiring costs at least for fixed-term contracts.

¹³ Bassanini et al. (2017) provide evidence that this assumption holds in French data.

case of hiring on (or termination of) fixed-term contracts, as long as it remains smaller than in the case of dismissals - see Appendix A.1.4.

Social sanctions occur if the dismissal is perceived as harmful by the community of the headquarters. Because this perception is not necessarily the same if a dismissal takes place within the community itself or at a more distant place, we allow the level of social sanction (denoted S_j) to depend on the distance to the firm's headquarters. The relationship between distance and social sanctions by the headquarters' community is likely to vary with how much a community cares about dismissals of other people. In the model, we consider two types of communities, self-centered and outward-looking. Self-centered communities care only about shocks (incl. dismissals) affecting their members or other communities with which they interact. There may be two reasons for this pattern of preferences: either members of the community care about what happens to co-members because this directly enters their utility function as an argument (they are to some extent altruistic towards their co-members) or because this has an impact on a variable affecting their own utility (they are selfish but the fate of their co-members impacts one of the arguments of their utility function). Whatever the mechanism at work, the more intense the interactions between individuals living at headquarters and individuals living in another community, the greater the social sanctions imposed on the CEO in the case of dismissals of members of this other community. In other words, in self-centered communities, the social sanction implied by a dismissal in establishment j is an increasing function of the intensity of the interactions between the community where the job is destroyed and the community where the firm's headquarters are located. To the extent that social interactions decrease with geographical distance,¹⁴ S_j will be a decreasing function of distance from headquarters δ_j :

$$S_j = s - m(\delta_j) \quad [1.2]$$

where s is a constant and m is a monotonic increasing function. By contrast, outward-looking communities equally care about all shocks, wherever they take place. Therefore, they are equally concerned about dismissals, no matter where destroyed jobs are located, that is:

$$S_j = s \quad \forall j \quad [1.3]$$

¹⁴ Evidence that social relations decrease with geographical distance between individuals is provided by the *Contact entre les personnes* ("Contact between people") Survey, carried out by the French Statistical Institute (INSEE) in 1983. This survey has information on the frequency of encounters of an individual with his/her friends, children, parents and in-laws and the distance at which these relatives and friends live, for 17,797 couples of individuals. For distances higher than 5 km, the coefficient of correlation between distance and the frequency of encounters is -0.05 – significant at the 1% level.

In the following, we drop the establishment subscript to simplify the notation. Firms are wage-takers and workers are paid wage w .¹⁵ Assuming away discounting for simplicity, the CEO's expected utility from hiring on a permanent contract for a job with risk γ in a given establishment is:

$$U^o(\gamma) = \sum_{k=0}^{\infty} [(1-\gamma)^k(1-w)] - h^o - \sum_{k=0}^{\infty} (1-\gamma)^k \gamma (S + d^o) \quad [1.4]$$

The first two terms on the right-hand side stand for expected profits over the duration of the job, that is the sum of expected instantaneous profits, multiplied by the probability of job survival at time k , minus the contract writing cost h^o . The last term stands for the cost of separation that is the legal costs and the social sanction.¹⁶ Re-arranging equation [1.4] yields:

$$U^o(\gamma) = \frac{(1-w)}{\gamma} - c^o \quad [1.5]$$

where $c^o = d^o + S + h^o$. Social sanctions can be seen, therefore, as an additional adjustment cost beyond hiring costs and legal firing costs. By contrast, as discussed above, since fixed-term contracts are expected to terminate after a time span D , their termination involves no social sanction. The CEO's expected utility from hiring on a fixed-term contract is:

$$U^f(\gamma) = \sum_{k=0}^{D-1} (1-\gamma)^k - wD - h^f = \frac{1 - (1-\gamma)^D - \gamma wD}{\gamma} - h^f \quad [1.6]$$

In words, the expected utility that the CEO derives from a fixed-term contract is the difference between the expected output over the duration of the contract, and the sum of the wage bill paid during the whole contract (wD) and the contract writing cost h^f .

The firm chooses a permanent contract if $U^o(\gamma) \geq U^f(\gamma)$ as long as $U^o(\gamma) \geq 0$, and a fixed-term contract if $U^o(\gamma) < U^f(\gamma)$ as long as $U^f(\gamma) \geq 0$. As shown in Appendix A.1.1, both expected utilities in equations [1.5] and [1.6] are decreasing and convex in γ . We assume that when $\gamma = 1$ (that is, the job ends with probability one at the end of the first period), the fixed-term contract is the one yielding the greatest utility, even if this can be negative.¹⁷ Under this assumption, the difference in intertemporal utility $U^o(\gamma) - U^f(\gamma)$ is decreasing

¹⁵ For the sake of simplicity, we assume that wages and productivities do not depend on the type of contract. Because this would just create differences in per-period profits, it would not change the effect of distance on the choice of employment contract.

¹⁶ We thus assume that production is separable which is consistent with the fact that job risk on a given job is assumed to be independent from that of other jobs.

¹⁷ This is equivalent to assuming $1 - wD - h^f > 1 - w - c^o$. If this were not the case, the choice problem would be trivial: permanent contracts would be more attractive for the CEO for any value of γ , since – as shown in Appendix A.1.1 – expected utilities in equations [1.5] and [1.6] are decreasing and convex in γ and when $\gamma \rightarrow 0$, $U^o(\gamma) \rightarrow +\infty$, while this is not the case for $U^f(\gamma)$.

with the job risk and there is a unique job risk threshold, denoted $\bar{\gamma}$ hereafter, such that the firm hires on permanent contracts if $\gamma < \bar{\gamma}$ (see Appendix A.1.2). Intuitively, when the job risk tends to 0, the value of a permanent contract tends to infinity, while it goes to a finite value in the case of fixed-term contracts because job duration is fixed. Moreover, both values decrease with job risk, but less so for fixed-term contracts since at the end date they can be terminated at no cost – see Figure 1.

We consider now how contract choices are affected by the adjustment costs. An increase in adjustment costs on permanent contracts c^o reduces the contract-choice threshold $\bar{\gamma}$, that is:

$$\frac{d\bar{\gamma}}{dc^o} < 0.$$

The formal proof is provided in Appendix A.1.3 but it can be easily understood since an increase in adjustment costs for permanent contracts makes these contracts more expensive for any job risk γ , thereby making them less convenient. Graphically, the expected-utility curve for permanent contracts shifts downwards while changes in c^o do not affect the corresponding curve for fixed-term contracts, thereby resulting in a shift to the left of the cut-off point.

Let us assume that if $\gamma=1$ fixed-term contracts always yield a non-negative expected utility (we relax this assumption in Appendix A.1.5). In this case, the share of permanent contracts in new hires is simply $L^o = F(\bar{\gamma}, \delta)$ and that of fixed-term contracts is $L^f = 1 - L^o$. If adjustment costs on permanent contracts increase, the job-risk cut-off goes down and so does the probability of hiring on a permanent contract. In turn, this raises the share of fixed-term contracts in new hires:

$$\frac{dL^f}{dc^o} = -f(\bar{\gamma}, \delta) \frac{d\bar{\gamma}}{dc^o} > 0$$

where f stands for the density function of job risk γ . Since $c^o = h^o + d^o + S$, we have that $d\bar{\gamma}/dS = d\bar{\gamma}/dc^o$, which implies that potential social sanctions, which would occur in the case of dismissals of workers on permanent contracts, have an impact on hiring decisions in terms of contract choice:

$$\frac{dL^f}{dS} = -f(\bar{\gamma}, \delta) \frac{d\bar{\gamma}}{dc^o} > 0$$

In other words, the CEO tries to escape the threat of social sanctions – i.e. social pressure against dismissals – by reducing hiring on permanent contracts and resorting to fixed-term contracts, instead.

Because of imperfect information and monitoring problems, distant jobs are riskier (see equation [1.1] above), which tends to increase the share of fixed-term contracts in establishments that are located far away from the headquarters. However, because social sanctions can also change with distance, the overall relationship between the share of fixed-term contracts L^f and distance to headquarters is complex. The total derivative of the share of fixed-term contracts with respect to distance reads:

$$\frac{dL^f}{d\delta} = -f(\bar{\gamma}, \delta) \frac{d\bar{\gamma}}{dS} \frac{dS}{d\delta} - \frac{\partial F(\gamma, \delta)}{\partial \delta} \quad [1.7]$$

When the headquarters are located in an outward-looking community, social sanctions are independent of distance ($dS/d\delta = 0$) and the first term on the right-hand side of eq [1.7] is zero: the only effect of distance is the one occurring through monitoring and imperfect information, that is (see equation [1.1] above):

$$\frac{dL^f}{d\delta} = -\frac{\partial F(\gamma, \delta)}{\partial \delta} > 0 \quad [1.8]$$

which implies that the share of fixed-term contracts rises with distance when headquarters are located in outward-looking communities. In contrast, in self-centered communities, social sanctions induced by separations decrease with distance to the headquarters ($dS/d\delta < 0$). In this case, while the second term on the right-hand side is positive, the first one is negative, which results in an ambiguous sign of $dL^f/d\delta$. In other words, when the headquarters are located in a self-centered community, the threat of social sanctions counteracts the effect of monitoring and imperfect information. If the effect of social pressure against dismissals is large enough, the share of fixed-term contracts may even decline with distance.

So far, we have assumed that the firm is large enough so that the actions of the CEO are visible in the local community of the headquarters. If, in contrast, the firm is too small to be visible, equation [1.2] becomes:

$$S_j = 0$$

and is therefore a special case of [1.3]. In this case, inequality [1.8] holds whether the local community at headquarters is self-centered or outward looking.

To sum up, our model shows that the threat of social sanctions by the local community – i.e. social pressure – may generate a negative relationship between distance to headquarters and the share of fixed-term contracts in new hires, when headquarters are located in areas characterised by self-centered communities. By contrast, when the headquarters are located in areas characterised by outward-looking communities, social pressure does not vary with distance: the share of fixed-term contracts in new hires is then larger in distant establishments because they are more difficult to monitor and imperfect information on their local conditions increases the risk of negative shocks. The empirical validity of these predictions is investigated in the remainder of this paper.

2. The Econometric Model

2.1 Distance to Headquarters, Self-centeredness and Short-term Contracts

To investigate the role of social pressure on firms' hiring behavior, we estimate the following equation:

$$L^f_{jHt} = \beta_0 + \beta_1 Dist_{jHt} + X_{jHt}\beta_2 + EA_{jH} + D_t + D_H + \varepsilon_{jHt} \quad [2.1]$$

where L^f_{jHt} denotes the share of fixed-term contracts in new hires in establishment j of a firm with headquarters H at year t , $Dist_{jHt}$ is the distance of establishment j to the firm's headquarters at year t and X_{jHt} is a vector of establishment-level controls. EA_{jH} is a dummy variable for the employment area¹⁸ in which establishment j is located, D_t and D_H are year and headquarters dummies, respectively, and ε_{jHt} is an error term. By including both headquarters and employment-area fixed effects, we control for geographical characteristics of establishments and headquarters.

We estimate this equation on our full sample of firms and separately for firms with headquarters located in self-centered and outward-looking communities. Based on our model, we expect distance to headquarters to have a positive impact on the share of fixed-term contracts when headquarters are located in outward-looking communities since the (positive) effect of monitoring and asymmetric information is not counterbalanced by the effect of social pressure. In contrast, when headquarters are located in areas where local communities are self-centered, the overall effect of distance on the share of fixed-term contracts may be

¹⁸ Employment areas are travel-to-work zones defined on the basis of daily commuting patterns as observed at the beginning of the 1990s. Employment areas correspond to local labor markets and usually contain a city and its catchment area. There are 341 such areas in mainland France with an average size of 1,570 km².

negative if the impact of social pressure is strong enough. On the full sample of firms, the effect of distance is ambiguous.

We estimate equation [2.1] on secondary establishments only and hence exclude headquarters from our sample. The latter are indeed, by definition, at zero distance from themselves and are functionally different from secondary establishments so that they may have lower shares of fixed-term contracts.

Distance to headquarters, however, is likely to be endogenous. For example, because monitoring establishments located further away from headquarters is more difficult, firms will open and keep such establishments only if they have productive advantages that compensate monitoring costs. If performance is also correlated with the type of employment contracts, OLS estimates of [2.1] are likely to be biased. To address the potential endogeneity of distance, we rely on an instrumental variable (IV) strategy.

Following Bassanini et al. (2017), we instrument the distance between one establishment and its headquarters by the *potential distance* defined as the distance between the headquarters and the place where the establishment would have been located (its *potential location*) had this location been chosen only to maximise its contribution to the firm market potential (irrespective of other plant characteristics).

In economic geography, the market potential is a measure of the relative advantage of a location in terms of access to final demand (see Harris, 1954). It is defined as the sum of the purchasing capacities of surrounding local markets weighted by the inverse of their distance – which typically proxies transportation costs to customers. By analogy, we define the market potential of a multi-establishment firm F as:

$$MPF_F = \sum_k \frac{PC_k}{\min_{j \in F} \{Dist_{kj}\}}$$

where PC_k stands for the purchasing capacity of local market k and j indexes the establishments of the firm, including the headquarters. In other words, the market potential of firm F is the sum of the purchasing capacities of each local market weighted by the inverse of the distance ($Dist$) of these markets to the closest establishment of the firm. As is classical, we capture purchasing capacity by current population¹⁹ and local markets by French

¹⁹ In the economic geography literature, purchasing capacity is proxied either with income-based measures (see e.g. Combes, Mayer and Thisse, 2008) or with population-based measures (see e.g. Bottazzi and Peri, 2003; Ioannides and Overman, 2004 and Briant, Combes and Lafourcade, 2010). We use a population-based measure insofar as information on aggregate income is not available at the level of employment areas.

employment areas.

Let K_j denote the set of local markets for which j is the closest establishment among all establishments of firm F , i.e. for which $Dist_{kj} < \min_{i \in F \setminus \{j\}} (Dist_{ki})$ where $F \setminus \{j\}$ is the set of all establishments of firm F excluding j . Then, market potential MPF can be rewritten as:

$$MPF_F = \sum_{j \in F} \underbrace{\sum_{k \in K_j} \frac{POP_k}{Dist_{kj}}}_{CMPF_j}$$

where POP denotes population. $CMPF_j$ can be interpreted as the contribution of establishment j to the market potential of firm F . It can be seen as a proxy of the relative size of the local demand served by each establishment of F .

Once the contribution to the firm market potential is defined in this way, for each establishment of each firm in our sample, we identify the employment area where this establishment should have been located to maximise its contribution to the firm market potential. We call it the *potential location* of the establishment.²⁰ Formally, the *potential location* of establishment j (PL_j) is defined as:

$$PL_j = \operatorname{argmax}_h \{CMPF_h\} = \operatorname{argmax}_h \left\{ \sum_{k \in \left\{ Dist_{kh} < \min_{i \in F \setminus \{j\}} (Dist_{ki}) \right\}} \frac{POP_k}{Dist_{kh}} \right\} \quad [2.2]$$

where h indexes the employment areas. One concern here could be that the population we use to compute $CMPF$ is not pre-dated with respect to our sample. To overcome this problem, as suggested by the literature in economic geography, we use local terrain ruggedness as an exogenous predictor of local population.²¹ The underlying assumption is that more rugged locations are less inviting so that fewer individuals settle there. Taking the maximum value of ruggedness in our data minus the effective ruggedness of the area as an exogenous proxy of

²⁰ In practice, for each firm in our sample, we pick up one of its secondary establishments and remove it. We then consider each employment area in France and consider what would be the contribution to the firm market potential if an additional plant were located there. We take the employment area that maximises this contribution: this is the potential location. In doing so, we consider all the establishments of firm F in France (see col. (2) of Table A6) and not only the establishments belonging to our regression sample. For the computation, we assume that all establishments of F are located at the barycenter of their region. This simplifying assumption allows us to save substantial computational time, since some of our firms have hundreds of establishments.

²¹ See Combes et al. (2010) and Nunn and Puga (2012).

population,²² PL_j can be written as:

$$PL_j = \operatorname{argmax}_h \left\{ \sum_{k \in \{Dist_{kh} < \min_{i \in F \setminus \{j\}} (Dist_{ki})\}} \frac{RUG_{max} - RUG_k}{Dist_{kh}} \right\}$$

where RUG_k denotes ruggedness of the employment area k and RUG_{max} is the maximum ruggedness over all employment areas. We then compute the distance between the potential location and the location of the firm's headquarters, which we call *potential distance*.

To qualify as a valid instrument, potential distance must affect the share of fixed-term contracts in hiring only through actual distance, and should therefore be unrelated with any unobserved plant-specific characteristics that can affect fixed-term contracts after conditioning on actual distance. Given that the potential location has been constructed only using information on local demand, the only reasons why potential distance may affect the share of fixed-term contracts is either through actual distance or because it could be correlated with local demand. Yet, as shown in Table A1, potential distance is uncorrelated to local demand, as measured by the *CMPF*.²³ This suggests that the orthogonality condition required for instrument validity holds for the potential distance.²⁴

Finally, given that our instrument is based on final demand, the compliers are multi-establishment companies producing for the final market, rather than intermediate-good or service producers. This could, in principle, make our instrument weak. As evidenced in Section IV, this is not the case.

2.2 Firm visibility and CEOs' place of living

The literature on social pressure suggests that it affects individuals' decisions only when they are visible (Della Vigna et al., 2012; Gerber et al., 2008; Funk, 2010). In our setup,

²² Following Combes et al. (2010), local terrain ruggedness is defined here as the mode of maximum altitudes across all pixels in an employment area minus the mode of minimum altitudes, using pixels of 1 km by 1 km. The correlation between ruggedness and population across employment areas is significant at the 1% level in our data.

²³ In contrast, the actual distance to headquarters turns out to be positively correlated with *CMPF*: the coefficient of correlation is as high as 0.15 and significant at the 1% level – see Appendix Table A1. This suggests that establishments located far away from their headquarters are selected on their contribution to the firm's market potential. As a consequence, OLS estimates of equation [2.1] are likely to be biased.

²⁴ An alternative would be to construct potential distance replacing POP_k by an arbitrary constant in equation [2.2]. This instrument would be orthogonal by construction. When local demand is uniformly distributed, firms indeed maximise their market potential by locating establishments so that their contribution to the market potential is equal. This implies that potential distance is uncorrelated with the *CMPF* in the potential location and hence with the *CMPF* in the actual location. As shown in Appendix Table A9, our results are robust to using this instrument although it is not our preferred one since it contains less information.

this suggests that CEOs will be subject to social pressure against dismissals arising from the local community of their headquarters only when their firm is visible in that community. We test this prediction by estimating the following equation:

$$L^f_{jHt} = \beta_0 + \beta_1 Dist_{jHt} * HV_{Ht} + \beta_2 Dist_{jHt} * LV_{Ht} + X_{jHt} \beta_3 + EA_{jH} + D_t + D_H + \varepsilon_{jHt} \quad [2.3]$$

where HV_{Ht} is a dummy variable capturing the fact that the firm is highly visible in the employment area of its headquarters and LV_{Ht} is a dummy variable capturing low visibility of the firm at headquarters. Since visibility is likely to be correlated with firm size, we control for the interactions between distance to headquarters and a set of dummies of firm size (both in the whole country and in the employment area of the headquarters). We expect β_2 to be positive: the impact of distance to headquarters on the share of fixed-term contracts should be positive when the firm is hardly visible at headquarters since, in this case, the social pressure effect is expected to be negligible and the monitoring/asymmetric information effect should dominate. In contrast, when the firm is highly visible at headquarters, the impact of distance (i.e. β_1) is ambiguous since the positive impact due to monitoring or asymmetric information will be counterbalanced by the negative impact of social pressure.

We estimate equation [2.3] both on our full sample and separately on firms with headquarters located in self-centered and outward-looking communities. When the firms' headquarters are located in outward-looking communities, the effect of social pressure does not vary with distance, so we expect the impact of distance to headquarters on the share of fixed-term contracts in hiring to be positive and similar, whatever the degree of firm visibility. In contrast, this impact could be negative for firms that are highly visible at headquarters and with headquarters located in self-centered areas if the social pressure effect is strong enough.

CEOs are also likely to be more sensitive to the social pressure exerted by the local community at headquarters when they not only work but also live in that community. We have information on the CEO's place of living for a limited subsample of our data. We test this prediction by re-estimating equation [2.3] where the dummy variable for high/low firm visibility is replaced by a dummy variable capturing whether or not the CEO lives in the community of the firm's headquarters. As for visibility, we do so on the full sample and separately on firms with headquarters located in self-centered and outward-looking communities. On the full sample, we expect the impact of distance on the share of fixed-term contracts to be more positive if the CEO does not live in the community of the headquarters. In this case, the effect of monitoring and asymmetric information is indeed likely to dominate

that of social pressure. When estimating our model on the sample of firms with headquarters located in outward-looking communities, we expect the impact of distance to be positive whatever the CEO's place of living, since the only effect varying with distance is that of monitoring and asymmetric information. In contrast, when headquarters are located in self-centered communities, the impact of distance should be more negative when CEOs live in the community of the headquarters as compared to when they do not.

3. The Data

The data that we use come from matching several data sources. The first one is the social security records – the DADS, *Déclarations Annuelles de Données Sociales* over the period 1997-2009. They cover the universe of establishments and firms in all industries except agriculture, part of the food-processing industry and rural financial institutions (e.g. Crédit Agricole). They have yearly information on the municipality (or *arrondissement*²⁵) where the establishment is located as well as its age and industry. They also provide the number of employees as well as the gender and (1-digit) occupational structure of the workforce as of December 31st of each year. Therefore, we lag these variables by one year to use them as controls in our regressions.

For each establishment in the DADS, we know the identifier of its headquarters and the municipality/*arrondissement* where they are located. To the extent that 8.2% of our establishments change headquarters over the period under study, the location of the headquarters will be time-varying in our data. The DADS also has information on the legal category of the firm to which the establishment belongs (business company, public administration, charity etc.).

The visibility of a firm in the employment area of its headquarters is assumed to be an increasing function of its share of local employment. As can be seen in Appendix Table A2, the distribution of the shares of firms' employment in the employment area of their headquarters is quite skewed. So, in our empirical analysis, we capture high visibility with a dummy variable equal to 1 when the firm belongs to the upper 25% of the distribution and 0 otherwise. Similarly, low visibility is captured by a dummy variable equal to 1 when the firm belongs to the lower 75% of the distribution and 0 otherwise.

²⁵ *Arrondissements* are subdivisions of municipalities. They exist only for the three largest French cities: Paris, Lyon and Marseille.

The second source that we use is the DMMO/EMMO databases. The DMMO (*Déclarations sur les Mouvements de Main-d'Oeuvre*) has exhaustive quarterly data on gross worker flows for establishments with 50 employees or more. The EMMO (*Enquête sur les Mouvements de Main-d'Oeuvre*) has similar information on a representative sample of 25% of the establishments with 10 to 49 employees.²⁶ Both databases have information on hiring flows (excluding temporary agency workers) and the type of contract on which employees are hired.²⁷ We compute the shares of fixed-term contracts in hiring for each quarter over 1998-2009. Given that firms' headquarters only vary on a yearly basis, we then aggregate the share of fixed-term contracts in hiring at the year level.

The *Répertoire Géographique des Communes*²⁸ provides information on the latitude and longitude of municipalities. Similar information for the *arrondissements* of Paris, Lyon and Marseille has been gathered from the website *Carte de France*.²⁹ Great-circle distances between establishments are computed assuming that each establishment is placed at the barycenter of the municipality/*arrondissement* to which it belongs. This is, of course, a simplifying assumption. However, given that the largest cities are divided into *arrondissements* and that there are 36,570 municipalities in France – of which only 0.04% have a surface larger than 190 km² – the error we are making on the actual location is very small.³⁰ Given our definition of distance, the distance between two establishments located in the same municipality/*arrondissement* is zero by construction. We also have information on the 94 *départements* to which municipalities belong and the *Base Communale des Zones d'Emploi* allows us to know in which employment area each municipality is located.³¹

Our key measure of self-centeredness of the area where the firm's headquarters are located is based on the differential turnout rates at local versus national elections. The underlying assumption behind this measure is that more self-centered individuals will be relatively more concerned by local stakes than by national ones, so that their participation to local elections (as compared to national ones) will be higher. In the literature, election turnout is classically considered as a measure of civic engagement (Guiso, Sapienza and Zingales, 2004). To the extent that we want to capture self-centeredness rather than civic attitude, we

²⁶ We do not have any information on worker flows for establishments with less than 10 employees.

²⁷ The type of contract is not available for transfers. So, we cannot include them in our analysis.

²⁸ This database is produced by the French *Institut National de l'Information Géographique et Forestière* (IGN).

²⁹ <http://www.cartesfrance.fr/>

³⁰ All French municipalities but nine are no larger than a square of 14x14 km. Therefore, assuming that establishments are located at the barycenter implies that the maximum possible error for these 36,561 municipalities is less than 10 km.

³¹ This database is provided by the French Statistical Institute (INSEE).

use the *difference* between two turnout rates that are likely to be influenced in similar ways by individuals' civic engagement. Election turnout rates are provided by the French Ministry of Interiors for all French *départements*. We proxy self-centeredness with the difference between the *département*-level turnout rates (in % of registered voters) at the first round of the 2001 municipal elections and at the 2000 national referendum (on the 5-year – instead of 7-year – term for the President of the Republic). We use the 2000 referendum rather than the 2002 parliamentary elections since French Members of Parliament (MP) are elected through a first-past-the-post system. Constituencies are rather small and candidates often represent local interests: many of them also have a local mandate – as mayor or member of the *département* council – which they can maintain once elected as MP. As a consequence, election turnout in parliamentary elections is partly motivated by local stakes, in addition to national ones.

We validate our proxy of self-centeredness using a more standard measure provided by the 2008-2010 wave of the European Value Study (EVS). This survey covers 47 countries including France and provides information on political engagement and moral values of individuals. It is commonly used in the literature in sociology to contrast individuals caring essentially about their close relations to individuals caring about humanity as a whole (Rimac and Zrinscak, 2010; VanHeuvelen and Robinson, 2017; Waytz et al, 2019). People are indeed asked: "Do you feel concerned about: (1) Immediate family, (2) People in the neighborhood, (3) Human kind?". Answers range from 1 to 5 corresponding to "not at all", "not so much", "to a certain extent", "much", "very much". We measure self-centeredness by the difference between the average score obtained by the individual when answering questions (1) and (2) and the score obtained when answering question (3). We do not use this measure in our main analyses since we cannot compute the average self-centeredness in the *département* where the individual lives at the time of the survey. The survey indeed only reports the administrative region (which contains several *départements*) where the individual lives in 2008-2010 and the *département* in which he or she was living at age 14. Moreover, for most of these *départements*, the number of observations is very small.³² We use this information to check that differential election turnout properly captures self-centeredness. In Appendix Table A3 – Panel A, we regress individual self-centeredness as measured in the EVS on the average differential election turnout in the individual's region of residence and cluster standard errors at the regional level. As evidenced in column (1), the raw correlation is positive and significant at the 1% level. When adding controls for gender, age (6 classes), education (3

³² On the subsample of individuals who have not changed region of residence since age 14, 6 *départements* have no observations and only 49% have at least 10 observations.

classes), employment status (8 classes) and household income (12 classes), the point estimate slightly increases and remains significant at the 1% level – see col (2). Including additional controls for whether the individual would vote if general elections would take place the day after and for how often the individual discusses political matters with friends (never, sometimes, often) does not change the results – see col (3). This suggests that differential election turnout between local and national elections computed at the regional level is strongly correlated with individual self-centeredness as measured in the EVS. As a robustness check, Table A3 – Panel B estimates the correlation between the EVS measure of individual self-centeredness and the average differential election turnout in the *département* where the individual was living at age 14 – on the subsample of individuals who have not changed region of residence since age 14. The results are highly similar to those in Panel A. These findings provide evidence that differential election turnout is a good proxy of self-centeredness.

To build the measure of self-centeredness that we use in our regressions, we attribute headquarters to the *département* where they are located and rank them according to the level of differential election turnout in their *département*. We then partition headquarters according to their rank in two groups of equal size, i.e. using the median of the distribution of differential election turnout across headquarters as the cut-off point. We consider the *département* of the headquarters as “self-centered” when the difference in turnout rates between municipal and national elections is above the median and “outward-looking” otherwise. Descriptive statistics for differential turnout rates are provided in Appendix Table A4. The difference is positive all over the distribution, indicating that election turnout was systematically higher at the 2001 municipal elections than at the 2000 national referendum. The distribution of differential turnout rates across *départements* is provided in Appendix Figure A1.

We also build a secondary measure of self-centeredness based on charity donations. The underlying assumption is that outward-looking individuals will be more prone to make donations. The advantage of this measure is that we have access to historical data on charity giving. This allows us to make sure that our results are not driven by a correlation between local economic conditions, self-centeredness and the share of fixed-term contracts in hiring. However, a key drawback of this measure is that it may not properly capture self-centeredness to the extent that self-centered individuals may be generous if they are sure that their donations are used for local purposes. If this is the case, our measure of self-centeredness will

be somewhat noisy. The data we use come from the 1890 *Annuaire Statistique de la France*, from which we compute the total *département*-level receipts of secular charity centers as of 1887. Data are missing for a few *départements*³³ because their borders have changed since the 19th century. We standardise these donations by *département* GDP³⁴ – see Appendix Table A4. We classify *départements* into two groups, selfish and generous, using the same criteria as for election turnout, i.e. the median of the charity distribution across headquarters. This grouping represents an imperfect alternative to the self-centered/outward-looking grouping.

We match these data sources and keep all business companies – excluding non-profit organizations (charities, foundations, etc.) and public administrations. We only keep firms with at least two secondary establishments in our dataset³⁵ since we compare the shares of fixed-term contracts across firms' secondary establishments. We drop establishments for which the proportion of fixed-term contracts in hiring or some of our establishment-level controls are missing. The distribution of headquarters by employment area is presented in Appendix Figure A2. As standard in the literature in economic geography (e.g. Combes et al, 2010), we exclude establishments with headquarters located in the Paris area and its close suburbs (the so-called "*Petite Couronne*"). France being a highly centralised country, these headquarters represent more than 30% of all headquarters in France. We want to avoid that these might drive our results, all the more that Paris and its close suburbs turn out to be systematically outward-looking areas.³⁶ Our final sample contains 23,126 distinct establishments belonging to 4,954 different firms.

Starting in 2003, the DADS dataset also allows us to determine where CEOs live to the extent that they are wage-and-salary employees of their firm. Unfortunately, in France, this is not always the case since CEOs may alternatively be *mandataires sociaux* who are assimilated to self-employed from the point of view of social security and are hence out of the scope of the DADS. So, we have information on the CEOs' place of living only for a fraction of the observations in our preferred sample, namely 2,019 firms covering 7,015 establishments. We use these data to construct a dummy variable equal to 1 if the CEO lives

³³ Moselle, Meurthe-et-Moselle, Haut-Rhin, Bas-Rhin, Territoire de Belfort, Paris, Hauts-de-Seine, Seine Saint-Denis, Val de Marne, Essonne, Val d'Oise and Yvelines.

³⁴ Note that the ratio of historical donations to GDP is correlated with the current (2003-2010) ratio of charity donations to taxable income (computed at the level of *départements*). The estimated correlation coefficient is 0.22, statistically significant at the 5% level of confidence. The source of current charity donations and taxable income is the French Ministry of Finance. Historical *département*-level GDP is provided by Delafortrie and Morice (1959). It is measured as of 1864, which is the year closest to 1887 for which such information is available.

³⁵ These establishments may not be observed the same year. For example, in the case of 2 establishments, one of them may be observed at one year and the other one at another year.

³⁶ Putting Paris and close suburbs back into the sample yields qualitatively similar results.

within 50 km from the firm's headquarters and 0 otherwise. Symmetrically, we define a dummy variable equal to 1 if the CEO lives further away from the headquarters and 0 otherwise. In this subsample 74.6% of CEOs live and work at the firm's headquarters.

Descriptive statistics of our main regression sample are provided in Appendix Table A5. The unweighted average share of fixed-term contracts amounts to about 57.5% of hiring in our data. To get a picture of aggregate hiring flows, we can compute the weighted sum of the number of hires on fixed-term contracts over all establishments for each quarter and divide it by the weighted sum of all hiring in all establishments.³⁷ The resulting aggregate figure is 73.2% which is very close to the one provided by the French Ministry of Labor for the period 1999-2009 for the whole of France, i.e. 71.8% – see DARES (2015). The gap between the aggregate and the unweighted figures suggests that large establishments (with large hiring volumes) are characterised by shares of fixed-term contracts that are larger than average.

Given that our model estimates the impact of distance to headquarters on the share of fixed-term contracts controlling for headquarters fixed effects, we want to make sure that the variation in the share of fixed-term contracts across establishments of a given firm is large enough. To do so, we decompose the variance of this share between a within and a between-establishment component. The between component accounts for 77% of the variance, which is far from negligible.

The mean and median numbers of secondary establishments per firm and year in our sample are 3 and 1 respectively – see Appendix Table A6 – col (1). Over the period 1998-2009, the average number of headquarters per firm in our sample is 1.17. The average distance between secondary establishments and headquarters is 239 km – see Appendix Table A7. The mean distance to the closest establishment is 97 km, and 263 km to the farthest establishment.

4. Results

4.1 Main Results

³⁷ Using aggregation weights provided in the DMMO-EMMO.

Table 1 presents the IV estimates of the impact of distance to headquarters on the share of fixed-term contracts in hiring.³⁸ Our specification includes year dummies, headquarters fixed effects as well as a number of establishments' characteristics: establishment age (6 classes) and size (7 classes), the occupational and gender structure of the workforce, the firm size in the establishment's employment area (6 classes), 2-digit industry dummies, time-varying unemployment in the *département* where the establishment is located, employment-area fixed effects and 4 dummies for missing establishment in a given quarter. Controlling for establishment sector and age is important since this is a way to capture the level of risk that establishments are facing. Haltiwanger, Jarmin and Miranda (2013) indeed show that younger establishments are more volatile. If they are also located closer to headquarters – as evidenced by Neumark, Zhang and Ciccarella (2008) in the case of Wal-Mart supermarkets –, this could bias our results. Large plants may also be located closer to headquarters and we have remarked above that they tend to have a greater share of fixed-term contracts amongst new hires. By contrast, firms with several establishments in the same employment area, and therefore a large overall size in that area, may employ a larger share of individuals on permanent contracts to the extent that it may be easier for them to relocate employees to another plant in case of negative shock. This is why we control for both establishment size and firm size in the establishment's employment area. The occupational and gender structure of the workforce may also matter since women and unskilled employees may be more likely to be on fixed-term contracts. Finally, we control for time varying unemployment because, beyond time-invariant characteristics of local labor markets, establishments located in more dynamic areas may be more likely to have larger shares of fixed-term contracts.

As indicated by the first-stage coefficients, whatever our specification, potential distance to headquarters is strongly correlated with actual distance so that our instrument is not weak – see Table 1.

Column 1 of Table 1 presents the second-stage estimates on our full sample of observations. The impact of distance to headquarters on the share of fixed-term contracts is

³⁸ OLS estimates of equation [2.1] are presented in Table A8 in the Appendix. For establishments of firms with headquarters in outward-looking/generous *départements*, the impact of distance to headquarters on the share of fixed-term contracts in hiring is virtually zero – see Table A8 cols (2) and (4). This is due to the fact that, when estimated by OLS, this relation suffers from selection bias since establishments located far away from headquarters undergo the most serious monitoring problems so that they may not survive or may not even be created. This generates a downward bias in the estimates. In contrast, for establishments of firms with headquarters located in self-centered/selfish *départements*, the point estimate on distance is negative and significant – see Table A8 cols (3) and (5).

small and insignificant at conventional levels. This is not inconsistent with our theory. To the extent that our sample is composed of firms with headquarters located in both self-centered and outward-looking communities, the average impact of distance to headquarters on fixed-term contracts results from two counteracting effects – i.e. monitoring/asymmetric information and local social pressure – which makes it ambiguous. When considering separately establishments of firms with headquarters located in self-centered/selfish and outward-looking/generous *départements*, the pattern of impact of distance to headquarters on the share of fixed-term contracts in hiring is opposite across firm types. For establishments with headquarters located in outward-looking *départements* as measured on the basis of differential turnout at the local and national elections, distance to headquarters has a positive and significant impact on the share of fixed-term contracts in hiring – see Table 1, col (2). In the absence of social pressure aiming at protecting jobs located close to headquarters, the only effect that is at play is that of asymmetric information and monitoring: since establishments located further away from headquarters are harder to manage, they face more frequent shocks and hence rely more on fixed-term contracts when hiring. In contrast, for establishments with headquarters located in self-centered *départements*, local social pressure plays an important role, beyond monitoring problems. As a matter of fact, the impact of distance to headquarters on the share of fixed-term contracts turns out to be negative and the point estimate in Table 1, col (3) is significantly different from the corresponding one in col (2) at the 0.1% level.³⁹ This suggests that the pressure exerted by the local communities at headquarters in order to avoid dismissals at short distances overcomes the effect of monitoring and asymmetric information.⁴⁰ As a consequence, establishments located closer to headquarters hire more on fixed-term contracts. From a quantitative point of view, our results imply that when distance to headquarters increases by one standard deviation (218.9 km), the share of fixed-term contracts decreases by 6 percentage points (218.9×0.0273) – see col (3) –, i.e. by 10.3% as measured at the sample average (57.5%), which is far from negligible.⁴¹

³⁹ As shown in Appendix Table A9, these findings are robust to using, as an instrument, a measure of potential distance constructed using an arbitrary constant instead of ruggedness – see footnote 24.

⁴⁰ As a robustness check, we augment our specification including occupation-by-employment area dummies and occupation-by-*département*-by-year dummies. To do so, we reshaped our dataset. We define our observations at the occupation-by-establishment-by-year level where the occupational categories we consider are managers, board members and professionals, technicians, clerks, skilled blue-collars and unskilled blue-collars. Our dependent variable is in this case the share of fixed-term contracts in hiring within each occupation of each establishment at each year. Re-estimating our model with either of these two additional sets of controls leaves our results unchanged. Detailed results are available upon request.

⁴¹ These specifications include 51 industry dummies and 6 establishment age classes to control for the level of risk that establishments are facing. Our results are unchanged if we use either industry-by-time dummies or more detailed controls by including 719 industry dummies and 101 age classes (results available upon request).

Results are similar when self-centered/outward-looking attitude is proxied by selfishness/generosity as measured on the basis of historical charity donations – see Table 1, cols (4) and (5). To the extent that generosity has been shown to be correlated with income – Card, Hallock and Moretti (2010) – one could be concerned that these results capture differences in income per capita rather than self-centeredness across *départements*. This turns out not to be the case. If splitting our sample between high and low-income *départements* – rather than between generous and selfish *départements* – we indeed find no significant effect of distance on the share of fixed-term contracts in hiring neither when headquarters are located in high-income nor in low-income *départements*.⁴²

As discussed in Section 1, CEOs are likely to be subject to social pressure only if their firm is visible in the local community of their headquarters. To test for this prediction, we estimate equation [2.3] considering that a firm is highly visible when it accounts for a large share of employment in the employment area of its headquarters. Since firm visibility is likely to be strongly correlated with local firm size, we control for the interactions between distance to headquarters and a set of dummies of firm size in the employment area of the headquarters. In addition, since visibility may also be correlated with the overall size of the firm in France, we also include a control for distance to headquarters interacted with a dummy variable for large firms where large is defined as the top 25% of the distribution in the whole of France – results are however similar if these controls are not included. As shown in Table 2 col (1), when estimated on the full sample of establishments, the impact of distance on the share of fixed-term contracts in hiring is positive, although insignificant, for establishments of firms with low visibility. This is consistent with our theoretical framework, since for firms that are hardly visible at headquarters, social pressure is likely to be inexistent so that the effect of monitoring and asymmetric information problems dominates. This generates a positive relationship between distance to headquarters and the share of fixed-term contracts. In contrast, for firms that are highly visible at headquarters, the effect of social pressure is much stronger and offsets that of monitoring and asymmetric information. As a consequence, the impact of distance to headquarters on the share of fixed-term contracts turns out to be negative although not significant at conventional levels, and the difference in point estimates

⁴² The point estimate (resp. standard error) for distance is 0.0079 (0.0131) when estimated on the sub-sample of establishments with headquarters located in high-income *départements* and 0.0081 (0.0067) when estimated on establishments with headquarters located in low-income *départements*. Similarly to what has been done for self-centeredness and selfishness, the cut-off used to distinguish between the two groups is the cross-headquarters median of GDP per capita as computed from *département*-level data dated 1864.

between distance interacted with respectively high and low visibility is significant at the 5.2% level.

Results obtained when estimating our model separately on establishments of firms with headquarters located in self-centered and outward-looking *départements* are consistent with this pattern of results. When firms' headquarters are located in outward-looking *départements*, social pressure arising from the local community does not vary with distance so that the effect of monitoring and asymmetric information dominates – see cols (2) and (4) of Table 2: whatever the visibility of the firm at headquarters, the point estimates of distance to headquarters are positive and not significantly different from each other. In contrast, for firms with headquarters located in self-centered *départements*, social pressure plays an important role when the firm is highly visible at headquarters – see cols (3) and (5): in this case, the impact of distance on the share of fixed-term contracts is negative and significant at the 5% level. This confirms that establishments located close to headquarters tend to hire more on fixed-term contracts as a way to escape social pressure when their firm is highly visible at headquarters and the latter are located in a self-centered community. Conversely, whenever local communities at headquarters are self-centered but the firm is not visible, the impact of distance on the share of fixed-term contracts in hiring is positive although insignificant.

We also expect CEOs to be more sensitive to social pressure when they not only work but also live in the community of the firm's headquarters. To test for this prediction, we re-estimate equation [2.3], substituting dummy variables for CEOs living/not living at headquarters for firms' high/low visibility. When estimating our model on the full sample of establishments, the impact of distance on the share of fixed-term contracts in hiring is positive (significant at the 1% level) when CEOs do not live at headquarters – see Table 3, col (1). In this case, their sensitivity to social pressure is low so that the effect of monitoring and asymmetric information dominates, which generates a positive relationship between distance to headquarters and the share of fixed-term contracts. In contrast, when CEOs live at headquarters they are more sensitive to social pressure, which counterbalances the effect of monitoring and asymmetric information. In this case, the impact of distance to headquarters on the share of fixed-term contracts turns out to be insignificant at conventional levels.

We then estimate our model separately on establishments of firms with headquarters located in outward-looking and self-centered *départements*. As expected, for firms with headquarters located in outward-looking *départements*, the impact of distance to headquarters on the share of fixed-term contracts is positive whatever the place of living of the CEO – see

Table 3, cols (2) and (4) – and the difference in point estimates between distance interacted with CEO living and not living at headquarters is not significant. This result holds whether we measure self-centeredness based on election turnout or charity giving. Conversely, for firms with headquarters in self-centered *départements*, distance to headquarters has a negative and significant effect on the share of fixed-term contracts when CEOs live at headquarters, while the effect is positive for CEOs not living at headquarters – see Table 3, cols (3) and (5) –, and the difference in point estimates between CEOs living and not living at headquarters is significant at least at the 6% level. These findings yield support to the hypothesis that CEOs are more sensitive to social pressure in the community of the headquarters when they live in that community.

4.2 Robustness Checks and Extensions

To the extent that the evidence we provide relies on separate estimates conducted on establishments of firms with headquarters located in self-centered vs outward-looking communities, one could be concerned that having headquarters located in one type of community or the other could be correlated with firm characteristics that could influence the relationship between distance and the share of fixed-term contracts. To tackle this issue, we estimate, on our full sample of observations, a model in which the share of fixed-term contracts is regressed on distance to headquarters interacted with the dummy variables for self-centeredness and outward-looking attitude, controlling for a rich set of additional interactions between distance and a series of firm characteristics. These characteristics include the most important 1-digit industry within the firm, firm age, the occupational structure of the workforce, total firm size in France and the log average daily labor cost per worker as a proxy of firm productivity. In an alternative specification, we replace industry dummies with the standard deviation of firm employment growth within each 2-digit sector, in order to better capture the intrinsic level of risk in each industry. The results are provided in Appendix Table A11. To start with, columns (1) and (4) estimate a model which only includes the same baseline establishment-level controls as those used in Table 1. As expected, the results of this specification are similar to those in Table 1 – columns (2) and (3) for election turnout and (4) and (5) for charity giving –:⁴³ whatever measure of self-centeredness we use, distance has a positive and significant impact on the share of fixed-term contracts in establishments with

⁴³ In fact, the coefficients reported in Table 1 can be seen as the results of the estimation of a model in which each covariate has been interacted with dummies for self-centered and outward-looking *départements*. As such, the model underlying column (1) in Table A11 can be seen as a constrained version of the model underlying columns (2)-(3) of Table 1.

headquarters located in outward-looking *départements*, while its impact is negative and significant for establishments with headquarters located in self-centered communities. The difference in the point estimates of distance interacted respectively with outward-looking and self-centered communities at headquarters is also highly significant. When adding controls for distance interacted with firm characteristics, the results are essentially unchanged: both in the election turnout and the charity giving panels, distance has a negative impact on the share of fixed-term contracts when firms' headquarters are located in self-centered communities, while its effect is positive when firms' headquarters are located in outward-looking communities, with the difference in point estimates being highly significant – see columns (2), (3), (5) and (6). These findings suggest that the negative effect of distance on the share of fixed-term contracts that we find when headquarters are located in self-centered *départements* is unlikely to be due to specific firms locating their headquarters in this type of community.

Another worry could be that our measure of self-centeredness based on election turnout dates back to year 2001 and therefore is not pre-dated with respect to our sample, which spans from 1998 to 2009. This could be a problem if the difference in turnout rates between municipal and national elections is simultaneously correlated with local economic conditions and the share of fixed-term contracts in hiring. To overcome this problem, we re-estimate columns (2) and (3) of Table 1 on a reduced sample limited to years 2003-2009. The results are unchanged: the point estimate (resp. standard error) on distance is 0.0204 (0.0056) when headquarters are located in outward-looking communities and -0.0235 (0.0081) when headquarters are located in self-centered communities.

Given that our main measure of self-centeredness is based on the difference between turnout rates at local and national elections, a worry could be that whether a *département* turns out to be self-centered or outward-looking is entirely determined by its turnout rate at one of the two elections. In this case, our results could be due to differences in civic engagement across *départements* rather than to self-centeredness. To tackle this issue, we re-estimate equation [2.1] separately on *départements* with election turnout above and below the median at local elections – rather than with *differential* election turnout above or below the median. We find no significant effect of distance on the share of fixed-term contracts in hiring in either of the two subsamples.⁴⁴ The same goes when splitting our sample between

⁴⁴ The point estimate (resp. standard error) for distance is 0.0097 (0.0078) when estimated on the sub-sample of establishments with headquarters located in *départements* where election turnout is above the median at local elections, and 0.0066 (0.0074) when estimated on establishments with headquarters located in *départements* where election turnout is below the median at local elections.

départements with election turnout above and below the median at the national referendum.⁴⁵ This suggests that our main results are not due to local differences in civic engagement.

Since hiring costs are likely to vary with the skill level of the workers, we are interested in investigating whether the impact of local social pressure on the type of employment contract varies across high and low-skilled workers. To do so, we reshape our dataset and re-define our observations at the occupation-by-establishment-by-year level (see also footnote 40). Our dependent variable is in this case the share of fixed-term contracts in hiring within each occupation of each establishment in each year. We re-estimate the specification in Table 1 on these new data adding an interaction term between distance and a dummy variable indicating whether the occupation we consider is high or low skilled. The high-skill category includes managers, board members and professional. The low-skill category includes technicians, clerks and blue-collar. The point estimates on the Distance*High-skill and Distance*Low-skill variables are both negative and not significantly different one from the other.⁴⁶

Our theory relies on the assumption that adjustment costs associated to dismissals decrease as social ties get looser. So, an additional test consists in re-estimating our main specification on our main dataset using a measure of distance based on social ties rather than kilometers. We consider that an establishment is close to its headquarters when a high proportion of individuals living at headquarters were born in the geographical area of the establishment. When re-estimating our model with this measure of social distance, we find similar results to those obtained using physical distance – see Appendix A.3.

5. Discussion

5.1 Alternative Explanations

Could factors other than local social pressure account for the negative relationship that we find between distance to headquarters and the share of fixed-term contracts in hiring when firms' headquarters are located in self-centered communities? This is what we investigate in this subsection.

⁴⁵ The point estimate (resp. standard error) for distance is 0.0316 (0.0196) when estimated on the sub-sample of establishments with headquarters located in *départements* where election turnout is above the median at the national referendum, and 0.0087 (0.0090) when estimated on establishments with headquarters located in *départements* where election turnout is below the median at the national referendum.

⁴⁶ Results are available upon request.

One reason why firms could rely more on fixed-term contracts at short distance from headquarters is that there is no need to offer permanent contracts to attract high-productivity employees since the proximity with the firm's management is enough to make jobs attractive. This would generate a negative relationship between distance to headquarters and the share of fixed-term contracts in hiring. However, this relation should hold whatever the degree of self-centeredness of the local community at headquarters while we observe that this is the case only for firms with headquarters located in self-centered communities. For firms with headquarters in outward-looking *départements*, this relation is indeed positive and significant at the 1% level.

The negative relationship we find between distance to headquarters and the share of fixed-term contracts in hiring could also originate from workers' screening. Firms may be more selective when hiring workers closer to headquarters because the jobs at stake involve more responsibility. If, as suggested by Faccini (2014), temporary contracts are used as screening devices allowing firms to learn about workers' productivity, these contracts may be more in use closer to the firms' headquarters. However, here again, this relationship should hold whatever the degree of self-centeredness of the local community at headquarters, which is not the case in our results. Moreover, there is no reason that this relationship varies with firm visibility or with the place of living of the CEO.

Local employment subsidies may be another factor driving our results. They are typically given to firms (that are profit centers) and not establishments (that are not). If local authorities condition these subsidies on the fact that they are used for hiring workers locally, firms will hire more workers close to headquarters and, if they perceive the subsidies as temporary, the new hires will be on fixed-term contracts. This could account for the negative relationship between distance to headquarters and the share of fixed-term contracts in hiring. However, we do not find any impact of distance to headquarters on total hiring – see Table A10 –, even in establishments of firms with headquarters located in self-centered *départements*. This suggests that local subsidies are unlikely to explain our results.

Our finding that highly-visible firms tend to hire more workers on fixed-term contracts at short distance from headquarters could be due to the fact that these firms are large and hence have an important monopsony power on their local labor market. This would allow them to offer poorer job-quality employment contracts close to their headquarters. However, if this mechanism were a key driver of our results, this relation should hold whatever the degree of self-centeredness of the local community at headquarters. In contrast, we find this

effect only when headquarters are located in self-centered *départements*: when headquarters are located in outward-looking communities, we find that firms hire fewer workers on fixed-term contracts at short distance from headquarters and this effect does not vary whether firms are highly visible or not.

Firms with headquarters in rural areas could locate some specific functions (e.g. R&D) further away from headquarters as compared to what they would do if their headquarters were located in urban areas. If the corresponding employees tend to be employed on open-ended contracts and if self-centeredness correlates with rurality, this could generate a negative relationship between distance and the share of fixed-term contracts in hiring. In order to tackle this issue, we estimate, on our full sample of observations, a model in which the share of fixed-term contracts is regressed on distance to headquarters interacted with self-centeredness and outward-looking attitude on the one hand, and with a dummy variable for rural/urban *département* at headquarters as of year 2000, on the other hand. The corresponding results are presented in Appendix Table A12. Column (1) is identical to the first column of Table A11: it reports the results obtained when estimating a model which only includes the same baseline controls as in Table 1. The results are very similar when adding a control for distance interacted with a dummy variable for rural/urban *département* at headquarters – see col (2).

However, one could argue that rurality is a more continuous characteristic than what we capture with our dichotomous variable. To account for this possibility, we re-estimate the same model as in col (2) controlling for distance to headquarters interacted with other measures of economic development that could induce firms to locate R&D – or other highly-skilled functions – further away from their headquarters, i.e. GDP per capita in 2005, the employment share of the tertiary sector (excluding public administration) in 2000, the time-varying unemployment rate and the share of individuals aged 16 or more who are not in education and have a diploma higher than upper secondary education – see Table A12, col (3).⁴⁷ The results are very similar to those obtained in col (2): the impact of distance on the share of fixed-term contracts is negative and significant when headquarters are located in self-centered communities, while it is positive although insignificant when headquarters are located in outward-looking communities. This suggests that the negative effect of distance on

⁴⁷ Self-centeredness, rural/urban dummies and extended controls interacted with potential distance are used as instruments. The Angrist-Pischke F-test on Distance*Outward-looking is rather low (8.26 and 4.81, respectively) in columns (2) and (3). Given that our model has as many instruments as endogenous variables, it is just identified. As underlined by Angrist and Pischke (2009), just-identified 2SLS estimators are median-unbiased and confidence intervals are reliable except when the Angrist-Pischke F-test statistics are very close to 0, which is not the case here.

the share of fixed-term contracts that we find when headquarters are located in self-centered *départements* cannot be explained by rurality.

One could also worry that our results are not driven by local social pressure but rather by the fact that CEOs share the same values as their local community's. They would thus tend to be self-centered when the local community is so, and hence try to avoid dismissing workers at short distances from headquarters because they care for their local community. However, CEOs who care for their local community would not choose to hire workers on fixed-term rather than permanent contracts since the former entail greater job insecurity and hence lower job quality. This is all the more likely that, in contrast to the local community, CEOs do observe the type of employment contract they offer.

A last concern could be that our regressions could capture the effect of some geographic characteristics of the establishments located in the same *département* as their headquarters. By construction these establishments are at low distance from these headquarters. Moreover, their geographic characteristics could be correlated both with self-centeredness and with the propensity to use fixed-term contracts in that *département*. However, all our specifications include very detailed employment-area fixed effects, thereby netting out our estimates from any geographical effect of this type.

5.2 *The nature of social pressure*

If the negative relationship that we find between distance to headquarters and the share of fixed-term contracts in hiring when firms' headquarters are located in self-centered communities is due to local social pressure, can we be more specific about the nature of this social pressure? What exactly are the type of social sanctions CEOs are afraid of?

One possibility could be that CEOs are afraid of a boycott of their product or service by local consumers in the event they would lay off local employees and the community to which these belong is self-centered. For this mechanism to account for our results, it should be the case that firms sell most of their output close to their headquarters. Otherwise, large-scale boycotts would also occur in the communities of the secondary establishments in case of large dismissals, at least when these communities are self-centered. Unfortunately, data on the geography of firm sales are not available in France, which prevents us from testing this hypothesis. However, note that if the threat of a boycott by the local community at headquarters were the main driver of our results, the negative relationship between distance to headquarters and the share of fixed-term contracts in hiring should hold independent from

whether the CEO lives close to or further away from the headquarters. The results reported in Table 3 show that this is not the case. The share of fixed-term contracts in hiring is not larger closer to the headquarters when the CEO does not live there. The negative relation between distance and the share of fixed-term contracts that we uncover when the community at headquarters is self-centered only holds when the CEO lives close to the headquarters. This suggests that, although boycotts may occur when firms engage in mass dismissals, they are unlikely to account for our results.

When considering whether to dismiss employees close to the headquarters, CEOs may also worry that remaining employees who care about their co-workers may retaliate by reducing their effort – see Datta et al. (2010) and Drenszky and Heinz (2015). This may be particularly damaging to the firm if key functions are concentrated at headquarters. The fear of such sanction may lead CEOs to rely more on fixed-term contracts close to headquarters in order to avoid having to dismiss workers. However, here again, if this mechanism were at the core of our effect, the negative relationship between distance to headquarters and the share of fixed-term contracts should hold whether or not the CEO lives close to the headquarters. As mentioned above, this is not in line with the results presented in Table 3.

Pressure from local politicians to avoid dismissing workers at headquarters may also be of concern to CEOs. However, if this were the main driver of our results, we should not observe any negative relationship between distance to headquarters and the share of fixed-term contracts outside the region of the firm's headquarters since local politicians are likely to be indifferent to dismissals taking place outside their catchment area. This is not the case in our data. When re-estimating the specification used in column (3) of Table 1 on the subsample of establishments located outside the region of the firm's headquarters, we still find a negative point estimate (-0.032) significant at the 1% level. This suggests that, when self-centered, the local community at headquarters cares about dismissals all the more that they take place closer – and hence threaten individuals they have close contacts with – both within and beyond the administrative boundaries of the regions.

Ultimately, CEOs may be afraid of more "personal" forms of social sanctions such as a loss of reputation in their community which may be costly in terms of utility for them and/or their family. This interpretation is consistent with all our empirical findings. We indeed find that social pressure leads CEOs to hire employees on fixed-term contracts so as to avoid dismissals in the surroundings of the firm's headquarters only when they live close to the headquarters, i.e. when they belong to the local community. We also find that fixed-term

contracts represent a larger share of hiring in establishments located in communities with strong social ties with the community of the firm's headquarters – see Appendix A.3. These results support the idea that CEOs want to avoid dismissing workers wherever this will upset the members of their community for fear of the consequences this may bear for them and/or their relatives.

6. Conclusion

This paper has examined the impact of local social pressure on the choice of employment contracts. We have shown that for firms with headquarters located in self-centered communities, the share of fixed-term contracts in hiring is larger in establishments located closer to headquarters while the opposite holds for firms with headquarters located in outward-looking communities. These findings hold whether we use a measure of self-centeredness based on differential election turnout or we proxy it with selfishness based on charity giving. They are also robust to using a measure of distance to headquarters based on social ties rather than geography. We have also shown that the negative impact of distance to headquarters on the share of fixed-term contracts when headquarters are located in self-centered communities is concentrated on firms that are highly visible at headquarters and whose CEOs not only work but also live in the community of the headquarters. This suggests that when CEOs are subject to local social pressure against dismissals, they try to escape it by hiring workers on fixed-term contracts. We have shown that these findings are consistent with an adjustment-cost model of employment-contract decisions made by CEOs under the threat of local social sanctions. In contrast, they cannot be accounted for by alternative mechanisms involving workers sorting or screening, CEOs' altruism, local employment subsidies, monopsony power or geographical confounders.

Beyond fixed-term contracts, one could expect that other forms of employment that do not entail any commitment to long-term relationships, such as the use of independent contractors or temporary help workers, would represent alternative ways for CEOs to escape local social pressure. One could conjecture that establishments of firms with headquarters located in self-centered communities would make greater use of those contracts when located close to the firms' headquarters. Our data do not allow us testing this hypothesis but this would be a highly valuable contribution to our understanding of the development of non-standard forms of work.

In addition to local social pressure, firms' employment decisions are also likely to react to the threat of social sanctions on a larger scale, typically national or international. For example, the campaign against the use of child labor by Nike in 1996 indeed turned out to have substantially changed the human resource practices of the company since then.⁴⁸ Moreover, the growing development of social networks should, if anything, strengthen the impact of the national and/or international reputation of firms on their sales and ultimately on their profits. In this context, the effects of social pressure on firm behavior, including hiring and firing policies, could be even more important than what identified in this paper by focusing only on the local dimension of social pressure. Investigating this issue would be a fascinating avenue for future research.

Finally, since the evidence we provide is essentially indirect, more research is needed to qualify the nature of the social sanctions faced by CEOs. We have shown that the fear of local boycott or employees' retaliation, as well as political pressure, are unlikely to account for our results. In contrast, the fear of a reputational loss within one's own community is consistent with our findings. Detailed evidence of such reputational damage would decisively improve our understanding of CEOs' motivation as well as its consequences for firms' behavior.

Note – Models are estimated with 2SLS estimators. The dependent variable is the annual average share of fixed-term contracts in total hiring in percentage, as measured at the establishment level. Potential distance is used as an instrument. Actual and potential distances to headquarters are measured in kilometers. Control variables include establishment age (6 classes) and size (7 classes), occupational and gender structure of the establishment workforce, firm size in the establishment's employment area (6 classes), 2-digit industry dummies, time-varying unemployment at the *département* level, year dummies, 4 dummies for missing establishment in a given quarter and headquarters and employment-area fixed effects. Election turnout is measured as the difference between the *département*-level turnout rates (in % of registered voters) at the first round of the 2001 municipal elections and the 2000 referendum (on the 5-year – instead of 7-year – term for the President of the Republic). A firm is assumed to have headquarters located in an outward-looking *département* if its headquarters belong to the bottom half of the distribution of differential turnout rates. Symmetrically, firm headquarters are considered to be located in a self-centered *département* if they belong to the top half of the distribution. Charity giving is measured as the ratio of total charity donations in 1887 to *département*-level GDP. A firm is assumed to have headquarters located in a generous *département* if its headquarters belong to the top half of the charity giving distribution. Symmetrically, firm headquarters are considered to be located in a selfish *département* if its headquarters belong to the bottom half of the distribution. Robust standard errors clustered at the headquarters' *département* level in parentheses. *** p<0.01, ** p<0.05, * p<0.1.

Table 2 – Differential impact of distance to headquarters on the share of fixed-term contracts according to firm visibility at headquarters – IV estimates

Appendix

A.1. Theoretical appendix

Under the model's assumptions, the utility functions satisfy:

$$U_j^o(\gamma) = \sum_{k=0}^{\infty} (1-\gamma)^k (1-w) - h^o - \sum_{k=0}^{\infty} (1-\gamma)^k \gamma (S_j + d^o)$$

and

$$U_j^f(\gamma) = \sum_{k=0}^{D-1} (1-\gamma)^k - wD - h^f$$

We first show that they are both decreasing and convex in γ . Second, we characterize the risk level $\bar{\gamma}$ such that the CEO is indifferent between the two contracts and we demonstrate it is unique. Third, we show that it decreases with the adjustment costs on permanent contracts. We then consider a case where communities put pressure to hire workers on permanent rather than fixed-term contracts. Finally, we consider a case where risk distributions can shift with distance.

A.1.1. Utility functions are decreasing and convex in γ

Consider the utility derived by the CEO from a permanent contract:

$$U_j^o(\gamma) = \frac{(1-w)}{\gamma} - c^o$$

One gets

$$\frac{\partial U_j^o(\gamma)}{\partial \gamma} = -\frac{(1-w)}{\gamma^2} < 0$$

and

$$\frac{\partial^2 U_j^o(\gamma)}{\partial \gamma^2} = \frac{2(1-w)}{\gamma^3} > 0$$

In the same way, the utility from a fixed-term contract reads:

$$U_j^f(\gamma) = \sum_{k=0}^{D-1} (1-\gamma)^k - wD - h^f$$

Then

$$\frac{\partial U_j^f(\gamma)}{\partial \gamma} = - \sum_{k=0}^{D-1} k(1-\gamma)^{k-1} < 0$$

and

$$\frac{\partial^2 U_j^f(\gamma)}{\partial \gamma^2} = \sum_{k=0}^{D-1} k(k-1)(1-\gamma)^{k-2} > 0$$

A.1.2. Characterization of the risk threshold $\bar{\gamma}$

The risk threshold is defined by the indifference condition:

$$U_j^o(\bar{\gamma}) = U_j^f(\bar{\gamma})$$

First notice that both utilities are strictly decreasing and convex in γ . Then remark that:

$$\lim_{\gamma \rightarrow 0^+} U_j^o(\gamma) \rightarrow +\infty$$

$$\lim_{\gamma \rightarrow 0^+} U_j^f(\gamma) = D(1-w) - h^f$$

while

$$\lim_{\gamma \rightarrow 1} U_j^o(\gamma) = 1 - w - c^o$$

$$\lim_{\gamma \rightarrow 1} U_j^f(\gamma) = 1 - Dw - h^f$$

We only consider non-degenerate cases where $U_j^f(\gamma = 1) > U_j^o(\gamma = 1)$, that is where the fixed-term contracts are more profitable for the riskiest jobs. If it were not the case, permanent contracts would always be chosen.

Notice that we do not assume that utilities are positive for $\gamma = 1$ but that the *loss*, if any, is smaller under fixed-term contract than under permanent contract. Then, since both utilities are monotonic, decreasing and convex, and because:

$$\lim_{\gamma \rightarrow 0^+} U_j^o(\gamma) - U_j^f(\gamma) \rightarrow +\infty$$

and

$$\lim_{\gamma \rightarrow 1} U_j^o(\gamma) - U_j^f(\gamma) < 0$$

there is a unique risk threshold $\bar{\gamma}$. See Figure 1 for a graphical illustration.

A.1.3. The effect of adjustment costs c^o on contract choice

We have just demonstrated that there is a unique risk threshold $\bar{\gamma}$. Moreover, remember that both utilities are monotonic, convex and that the difference $U_j^o(\gamma) - U_j^f(\gamma)$ is such that, for the lowest risk level, the utility from permanent contract is higher than the utility from fixed-term contracts:

$$\lim_{\gamma \rightarrow 0^+} U_j^o(\gamma) - U_j^f(\gamma) \rightarrow +\infty$$

and, for the maximum risk level, the utility from permanent contracts is lower than the utility from fixed-term contracts:

$$\lim_{\gamma \rightarrow 1} U_j^o(\gamma) - U_j^f(\gamma) < 0$$

Then, in the vicinity of $\bar{\gamma}$:

$$\left. \frac{\partial(U_j^o(\gamma) - U_j^f(\gamma))}{\partial \gamma} \right|_{\gamma=\bar{\gamma}} < 0$$

Consider now the effect of a change in c^o . Differentiating $U_j^o(\bar{\gamma}) = U_j^f(\bar{\gamma})$, one gets:

$$\underbrace{\frac{\partial U_j^o(\bar{\gamma})}{\partial \bar{\gamma}} d\bar{\gamma} - \frac{\partial U_j^f(\bar{\gamma})}{\partial \bar{\gamma}} d\bar{\gamma}}_{<0} = dc^o$$

and thus

$$\frac{d\bar{\gamma}}{dc^o} < 0$$

An increase in the adjustment costs of the permanent contract decreases the threshold. Hence, distance reduces the threshold.

A.1.4. The effect of distance when communities put pressure to hire workers on permanent rather than fixed-term contracts

If communities put pressure on CEOs to hire workers on permanent rather than fixed-term contracts, the adjustment cost paid upon hiring would be the sum of the writing cost and the social sanction, which in turn would decrease with distance in self-centered communities. Denoting the overall adjustment cost with c^f , we have:

$$c^f = S^f + h^f$$

with $dS^f/d\delta \leq 0$. By substituting c^f for h^f in all the equations of the main text, it is easy to show that all the statements concerning the outward-looking case made in the main text as well as in Appendices A.1.1 and A.1.2 still hold, since in this case c^f , like h^f , does not depend on distance. Similarly, denoting with C the difference in overall adjustment costs between permanent and fixed-term contracts, that is $C = c^o - c^f$, and repeating the same proof as in Appendix A.1.3 but replacing c^o with C , we obtain:

$$\frac{d\bar{\gamma}}{dC} < 0$$

which implies:

$$\frac{dL^f}{dC} = -f(\bar{\gamma}, \delta) \frac{d\bar{\gamma}}{dC} > 0$$

and

$$\frac{dL^f}{d\delta} = -f(\bar{\gamma}, \delta) \frac{d\bar{\gamma}}{dC} \frac{dC}{d\delta} - \frac{\partial F(\gamma, \delta)}{\partial \delta}.$$

The first term on the right-hand side is different from zero only in the self-centered case, where C may vary as a function of δ . In that case the sign of $dL^f/d\delta$ is ambiguous as long as $dC/d\delta < 0$, that is as long as $dS/d\delta < dS^f/d\delta$, that is if the social sanction associated with dismissals decreases with distance more rapidly than the social sanction

associated with hiring on fixed-term contracts. Note that this condition always holds if the latter is equal to a fraction of the former, that is if $S^f = \alpha S$, with $\alpha < 1$.

A.1.5 The effect of distance when there is a maximum level of profitable risk

Consider that no job is profitable above a certain level, denoted with γ^{max} . That is

$$U_j^f(\gamma^{max}) = 0$$

since we work under the assumption that $U_j^f(\gamma = 1) > U_j^o(\gamma = 1)$ (non-degenerate case). Notice that the adjustment costs related to permanent contracts have no effect on the maximum risk level, that is:

$$\frac{\partial \gamma^{max}}{\partial c^o} = 0$$

The share of permanent contracts reads:

$$L^o = \frac{F(\bar{\gamma}, \delta)}{F(\gamma^{max}, \delta)}$$

where $F(\gamma^{max}, \delta)$ stands for the probability that the job is profitable and therefore the worker is hired. Then the effect of adjustment costs for permanent contracts satisfies:

$$\frac{\partial L^o}{\partial c^o} = \frac{f(\bar{\gamma}, \delta)F(\gamma^{max}, \delta) \frac{d\bar{\gamma}}{dc^o}}{F(\gamma^{max}, \delta)^2} < 0$$

We get the same effect as before: an increase in the adjustment costs for permanent contracts pushes the firm to be more selective and it decreases the risk threshold.

Looking at the effect of distance and allowing the distribution to shift with distance, one gets:

$$\frac{\partial L^o}{\partial \delta} = \frac{f(\bar{\gamma}, \delta)}{F(\gamma^{max}, \delta)} \frac{d\bar{\gamma}}{d\delta} \frac{dS}{d\delta} + \frac{F_2'(\bar{\gamma}, \delta)F(\gamma^{max}, \delta) - F(\bar{\gamma}, \delta)F_2'(\gamma^{max}, \delta)}{F(\gamma^{max}, \delta)^2}$$

When headquarters are located in an outward-looking community, social sanctions are independent of distance, $dS/d\delta = 0$, so that the above expression can be rewritten as:

$$\frac{\partial L^o}{\partial \delta} = \frac{F_2'(\bar{\gamma}, \delta)F(\gamma^{max}, \delta) - F(\bar{\gamma}, \delta)F_2'(\gamma^{max}, \delta)}{F(\gamma^{max}, \delta)^2}$$

The sign of the above expression is undetermined. Intuitively, when the distribution of risk shifts, more matches are unprofitable and thus both the number of permanent contracts and the number of fixed-term contracts change. However, $\partial L^o / \partial \delta < 0$ in outward-looking communities if $F'_2(\bar{\gamma}, \delta)F(\gamma^{max}, \delta) < F(\bar{\gamma}, \delta)F'_2(\gamma^{max}, \delta)$ which is a generalization of condition [1.1] when risk distribution can shift with distance. Since F is non-negative and $F'_2(\bar{\gamma}, \delta) < 0$, this generalized condition may not hold only if $F'(\gamma^{max}, \delta) < 0$, that is if, as distance increases, the probability that the worker is hired, and in large numbers the hiring rate, decreases. As shown in Table A10 in Appendix A.2, however, we find no evidence of this in our data.

A.2. Appendix Figures and Tables

Figure A1 – Difference between municipal and national elections' turnout rates in French départements, by quartile of the distribution

Note – Quartiles are computed on the cross-département distribution and ordered from the lowest to the highest.

Figure A2 – Number of headquarters in French employment areas, by quintile of the distribution

Note – Quintiles are ordered from the lowest to the highest.

Table A1 – Correlation between distance to headquarters and the contribution to the firm market potential

Panel B: Differential election turnout as measured in the department of residence at age 14			
Differential election turnout	0.0197** (0.0090)	0.0234** (0.0092)	0.0187** (0.0089)
Baseline controls	No	Yes	Yes
Extended controls	No	No	Yes
Observations	1,062	957	943
R-squared	0.0058	0.0421	0.0641

Note – OLS estimates. The dependent variable is built using the following questions from the European Value Study: "Do you feel concerned about: (1) Immediate family, (2) People in the neighborhood, (3) Human kind?" Answers range from 1 to 5 corresponding to "not at all", "not so much", "to a certain extent", "much", "very much". The dependent variable is the difference between the average score obtained when answering questions (1) and (2) and the score obtained when answering question (3). Baseline controls include gender, age (6 classes), education (3 classes), employment status (8 classes) and household income (12 classes). Extended controls include a dummy variable for whether the individual would vote if general elections would take place the day after and two dummy variables indicating how often the individual discusses political matters with friends. Election turnout is measured as the difference between the region/*département*-level turnout rates (in % of registered voters) at the first round of the 2001 municipal elections and the 2000 referendum (on the 5-year – instead of 7-year – term for the President of the Republic). Observations in Panel B include only individuals who live in the region where they were born. Robust standard errors clustered at the regional level (Panel A) and at the *département* level (Panel B) in parentheses. *** p<0.01, ** p<0.05, * p<0.1.

Table A4 – Distribution of *département*-level differential election turnout and charity giving across headquarters

<i>Variables</i>	
Difference (% points) between municipal and national elections' turnout rates	
Minimum	26.6
1 st quartile	31.7
Median	36.3
3 rd quartile	38.9
Maximum	51.1
Ratio of total charity donations to GDP (%)	
Minimum	0.047
1 st quartile	0.126
Median	0.181
3 rd quartile	0.260
Maximum	0.658

Table A5 – Descriptive statistics of observations in our sample

<i>Variables</i>	Mean	S.D.	<i>Variables</i>	Mean	S.D.
Share of fixed-term contracts (% in total hiring)	57.50	35.54	Structure of the workforce (% of plant employment)		
Quarterly hiring rate (% in total employment)	13.01	51.01	Managers	10.71	16.35
Establishment size (headcount)	111.39	208.89	Technicians and supervisors	21.55	19.96
Establishment age (years)	8.82	11.70	Clerks	29.92	32.41
Firm size in the employment area of establishment	254.39	628.77	Blue collars	37.82	34.17
Local unemployment rate (%)	8.19	1.95	Women	37.67	27.01
			Industries (%)		
			Agriculture	0.18	4.23
			Mining, Manufacturing, Energy	20.58	40.43
			Construction	9.59	29.44
			Services	69.66	45.97

Table A6 – Number of secondary establishments per firm by year

	(1) Establishments in our sample	(2) Establishments in France
1 st quartile	1	4
Median	1	7
Mean	3.0	23.6
3 rd quartile	3	15
Maximum	231	2,808

Note – Column (1) only includes establishments belonging to the regression sample. Column (2) includes all establishments of the firms in the regression sample, whether or not these establishments belong to that sample. The difference between the figures in columns (1) and (2) is due to three main reasons: our sample contains neither establishments with zero hiring in a given year nor establishments with fewer than 10 employees and it has no more than 25% of establishments with 10 to 49 employees.

Table A7 – Distance to headquarters

<i>Variables</i>	Mean	S.D.
<i>Distance in kilometers</i>		
Distance to HQ	239.0	218.9
Distance to HQ of the closest observation (within firm)	97.0	148.8
Distance to HQ of the median observation (within firm)	172.5	184.1
Distance to HQ of the farthest observation (within firm)	262.5	245.2

Note – Observations are establishment-year couples. The median observation is the observation that divides the within-firm distribution of distances in two equal parts. The mean (resp. standard deviation) of the median, the closest and the farthest distances to HQ are computed on the distribution of firms.

Table A8 – Impact of distance to headquarters on the share of fixed-term contracts – OLS estimates

Observations	73,601	73,601	73,601
R-squared	0.516	0.514	0.514

Note – Models are estimated with 2SLS estimators. The dependent variable is the annual average share of fixed-term contracts in total hiring in percentage, as measured at the establishment level. Actual and potential distances to headquarters are measured in kilometers. Baseline control variables include establishment age (6 classes) and size (7 classes), occupational and gender structure of the establishment workforce, firm size in the establishment's employment area (6 classes), 2-digit industry dummies, time-varying unemployment at the *département* level, year dummies, 4 dummies for missing establishment in a given quarter and headquarters and employment-area fixed effects. Election turnout is measured as the difference between the *département*-level turnout rates (in % of registered voters) at the first round of the 2001 municipal elections and the 2000 referendum (on the 5-year – instead of 7-year – term for the President of the Republic). A firm is assumed to have headquarters located in an outward-looking *département* if its headquarters belong to the bottom half of the distribution of differential turnout rates. Symmetrically, firm headquarters are considered to be located in a self-centered *département* if they belong to the top half of the distribution. Rural HQ is a dummy variable equal to 1 if the *département* of the headquarters was defined as mostly rural in 2000 in the OECD Regional Database. Extended controls include the following variables measured at the level of the *département* of the headquarters: GDP per capita in 2005, the employment share of the tertiary sector (excluding public administration) in 2000, the time-varying unemployment rate and the share of individuals aged 16 or more who are not in education and have a diploma higher than upper secondary education (source: French Statistical Institute). Self-centeredness dummies and extended controls interacted with potential distance are used as instruments. Robust standard errors clustered at the headquarters' *département* level in parentheses. *** p<0.01, ** p<0.05, * p<0.1.

A.3. Distance Based on Social Ties

The concept of distance that we have used so far is geographical (physical). We have assumed that, when headquarters are located in self-centered communities, as the distance between the establishment and its headquarters increases, social pressure decreases. The underlying assumption is that, as physical distance increases, social ties become looser, which tends to decrease social pressure and hence the adjustment cost associated with permanent contracts. To implement a more direct test of our theory, we use a concept of distance based on the intensity of social ties among communities. When doing so, we expect that, for headquarters located in self-centered communities, the share of fixed-term contracts in hiring will decrease with this measure of distance, i.e. when communities at headquarters and at plant are less strongly socially connected. Conversely, monitoring and asymmetric information problems should not vary with this measure of distance, except if the latter is strongly correlated with physical distance.

We take these predictions to the data by considering that an establishment is close to headquarters in terms of social ties when a high proportion of individuals living at headquarters were born in the geographical area of the establishment. We then estimate the following equation:

$$L^f_{jHt} = \beta_0 + \beta_1 SocDist_{jHt} + X_{jHt}\beta_2 + DE_{jH} + D_t + D_H + \varepsilon_{jHt}$$

where $SocDist_{jHt}$ is our proxy of the social distance of establishment j to the firm's headquarters and DE_{jH} is a dummy variable for the *département* in which the establishment is located. With this specification, we expect to find $\beta_1 < 0$ for firms with headquarters located in self-centered communities if social pressure against dismissals is strong enough.

To measure distance based on social ties, we use information from the French Labor Force Surveys for pre-sample years 1988 to 1997. More specifically, we consider the proximity between headquarters located in municipality A and a given establishment located in municipality B to be an increasing function of the average share of individuals living in the *département* of A who were born in the *département* of B. The underlying assumption is that the greater this proportion, the more important the social and family ties across the populations of both *départements*. This suggests taking the inverse of

proximity as a measure of distance. Yet, this is problematic since birthplace proximity is very concentrated around 0 (i.e. skewed) – see Figure A3.

Figure A3 – Density of Birthplace proximity

Note – Birthplace proximity is measured by the share of individuals living in the *département* of the headquarters who were born in the *département* of the establishment.

To overcome this problem, we rank all couples of *départements* from those with the highest (rank 1) to those with the lowest (rank 8,188) proximity. We define birthplace distance as the position in this ranking and use it as a measure of distance based on social ties. Unsurprisingly, birthplace distance turns out to be positively correlated with physical distance but this correlation is far from perfect (see Figure A4).

Figure A4 – Physical and Birthplace Distances

Note – Physical distance is measured in kilometers. We define birthplace proximity as the share of individuals living in the *département* of the firm headquarters who were born in the *département* of the establishment. We rank all couples of departments from those with the highest (rank 1) to those with the lowest (rank 8,188) proximity. Our measure of birthplace distance is the position in this ranking.

The results obtained when estimating our social distance equation are presented in Table A13 below. When estimations are run on the full sample of observations, the impact of birthplace distance on the share of fixed-term contracts in hiring is negative although insignificant – see col (1). This is consistent with what we obtain when estimating the model separately for firms with headquarters located in self-centered and outward-looking *départements*. Whatever the measure of self-centeredness we use, the impact of birthplace distance is positive but insignificant for firms with headquarters in outward-looking *départements* – see col (2) and (4). This is not surprising since a measure of distance based on social ties is less relevant than physical distance as regards monitoring problems. However, especially in col (2), we cannot exclude that the large standard error is due to the weakness of the instrument. By contrast, this relationship is negative and significant for firms with headquarters in self-centered *départements* – see col (3) and (5). These findings confirm that, as social pressure decreases with birthplace distance, adjustment costs on permanent contracts tend to be higher for establishments located in areas that are more socially connected to the area of the headquarters. This translates into the fact that these establishments rely more on fixed-term contracts whenever their headquarters are located in a self-centered community.

Table A13 – Impact of birthplace distance to headquarters on the share of fixed-term contracts – IV estimates

Dep.var:	(1)	(2)	(3)	(4)	(5)
